1 Objective

The primary objective of this assignment is to master the end-to-end process of creating, signing, and validating Bitcoin transactions using both **Legacy (P2PKH)** and **SegWit (P2SH-P2WPKH)** address formats.

Following are the technical goals:

- **RPC Infrastructure:** Establishing a secure connection to the `bitcoind` daemon in a **regtest environment** to programmatically manage wallets and transaction flows using the `python-bitcoinlib` or `bitcoinrpc` library.
- **Transaction Lifecycle:** Developing software to automate the generation of addresses, funding mechanisms through `sendtoaddress`, and the creation of raw transaction chains for both Legacy and SegWit formats.
- **Script Analysis:** Utilizing `decoderawtransaction` to dissect the structure of **Locking Scripts (scriptPubKey)** and **Unlocking Scripts (scriptSig)**.
- **Validation and Debugging:** Utilizing the **btcdeb Bitcoin Script Debugger** to perform a step-by-step logic trace of the challenge-response mechanism to verify that script execution resulting from concatenated input and output scripts resolves to TRUE.
- **Data-Driven Comparison:** Performing an empirical analysis of transaction efficiency by comparing **Physical Size (bytes)**, **Virtual Size (vbytes)**, and **Weight**, specifically identifying how Segregated Witness restructuring affects these metrics.
- **Protocol Benefits:** Evaluating the impact of **Segregated Witness** on transaction malleability and block space optimization through the separation of signature (witness) data and the application of the witness discount.

2 Environment Setup

The laboratory environment was established using a local Bitcoin Core node running in `regtest` mode within a **Windows Subsystem for Linux (WSL)** instance. This allows for instantaneous block generation and consistent POSIX-compliant script execution.

Figure 1: WSL Node Initialization and Environment Sync Flow

2.1 Bitcoin Core Configuration (bitcoin.conf)

The node must be configured to allow RPC communication. The following parameters were defined in the `~/.bitcoin/bitcoin.conf` file to ensure compatibility with the `python-bitcoinlib` library scripts.

```
# Core Network Settings
regtest=1
server=1

# RPC Authentication
rpcuser=user
rpcpassword=password

# Fee and Transaction Policy
paytxfee=0.0001
fallbackfee=0.0002
```

```
mintxfee=0.00001
txconfirmtarget=6

# Connection Settings
[regtest]
rpcport=18443
rpcallowip=127.0.0.1
```

2.2 Node Initialization and Terminal Execution

The Bitcoin daemon was executed in the background using the Linux-specific `-daemon` flag. To comply with modern Python packaging standards (PEP 668), a virtual environment was utilized to manage dependencies for the laboratory scripts.

```
karsh1708@Pacificblaster:~$ bitcoind -regtest -daemon
Bitcoin Core starting

karsh1708@Pacificblaster:~$ bitcoin-cli -regtest createwallet "test_wallet"
{
"name":  "test_wallet",
"warning":  ""
}

karsh1708@Pacificblaster:~$ python3 -m venv btc_env
karsh1708@Pacificblaster:~$ source btc_env/bin/activate
(btc_env) karsh1708@Pacificblaster:~$ pip install python-bitcoinlib
Successfully installed python-bitcoinlib-0.11.0
```

2.3 Connection Verification

The Python scripts interface with the node using the `bitcoin.rpc.RawProxy` class. The connection string facilitates access to the specific wallet instance created during initialization:

`http://user:password@127.0.0.1:18443/wallet/test_wallet`

This ensures that all RPC calls are context-aware and targeted toward the `test_wallet` data structures within the WSL layer.

3 Part 1: Legacy (P2PKH) Transaction Implementation

Figure 2: End-to-end Legacy Transaction Lifecycle Flowchart

3.1 Legacy P2PKH Python Script (part1_legacy.py)

The implementation below handles the full lifecycle of a Legacy transaction, including wallet management, P2PKH address generation, and the mandatory 101-block mining process to satisfy coinbase maturity requirements.

```
from bitcoin.rpc import RawProxy

# --- Configuration ---
rpc_user = "user"
```

```python
rpc_password = "password"
# Matches the wallet created in previous steps
proxy = RawProxy(service_url=f"http://{rpc_user}:{rpc_password}@127.0.0.1:18443/wallet
    ↪ /lab_wallet")

def execute_part_1_with_narrative():
    print("=====================================================================")
    print("ASSIGNMENT PART 1: LEGACY (P2PKH) TRANSACTION WORKFLOW")
    print("=====================================================================")

    # 1. Setup Wallet
    print("\n[STEP 1: WALLET INITIALIZATION]")
    try:
        proxy.createwallet("lab_wallet")
        print("-> Action: Created a new wallet named 'lab_wallet'.")
    except:
        print("-> Action: 'lab_wallet' already exists. Loading it into the daemon.")

    # 2. Generate Addresses
    print("\n[STEP 2: ADDRESS GENERATION]")
    addr_a = proxy.getnewaddress("Address_A", "legacy")
    addr_b = proxy.getnewaddress("Address_B", "legacy")
    addr_c = proxy.getnewaddress("Address_C", "legacy")
    print(f"-> Created Address A (Sender): {addr_a}")
    print(f"-> Created Address B (Intermediate): {addr_b}")
    print(f"-> Created Address C (Final Receiver): {addr_c}")

4 Part 2: SegWit (P2SH-P2WPKH) Technical Implementation

Figure 3: End-to-end SegWit Transaction Lifecycle Flowchart

4.1 SegWit P2SH Python Script (part2_segwit.py)

The following implementation manages the workflow for Segregated Witness transactions using P2SH-wrapped P2WPKH addresses. This approach ensures backward compatibility with the Bitcoin network while utilizing the witness data separation for increased efficiency.

```
from bitcoin.rpc import RawProxy
```

```python
# --- Configuration ---
rpc_user = "user"
rpc_password = "password"
# Ensure the wallet name matches your WSL setup (e.g., lab_wallet)
proxy = RawProxy(service_url=f"http://{rpc_user}:{rpc_password}@127.0.0.1:18443/wallet
    ↪ /lab_wallet")

def execute_part_2():

```

5 Script Validation

As required by the lab objectives, we utilized the Bitcoin Script debugger `btcdeb` to validate the execution flow. Validation is performed by concatenating the `scriptSig` (unlocking script) and the `scriptPubKey` (locking script). The debugger allows us to step through each operation to ensure the stack evaluates to a non-zero value (TRUE).

5.1 Legacy (P2PKH) Script Validation

In the P2PKH model, the unlocking script contains the ECDSA signature and the raw public key. The validation process follows a "Duplicate, Hash, Compare, and Check" flow.

```
(btc_env) karsh1708@Pacificblaster:~$ btcdeb "3044022025cefac2942970f31768b4b9fd0a01

<> PUSH 030a6d7b20...  to stack

script | stack
-----------------------------------------------------------------+-------
OP_DUP | 030a6d7b2037ccc...
OP_HASH160 | 3044022025cefac...
```

Explanation of Legacy Execution:

1. The **Signature** and **Public Key** are pushed onto the stack.
2. `OP_DUP` duplicates the public key.
3. `OP_HASH160` hashes the top public key, turning it into a PubKeyHash.
4. `OP_EQUALVERIFY` compares this hash against the one in the locking script (`f9b7a4...`).
5. `OP_CHECKSIG` uses the remaining public key and signature to verify the transaction's authenticity.

5.2 SegWit (P2SH-P2WPKH) Script Validation

In SegWit, the unlocking data is moved to the "Witness" field, reducing the transaction's virtual size. The debugger simulates the P2WPKH logic wrapped inside a P2SH script.

Explanation of SegWit Execution:
While the stack operations look identical to P2PKH in the debugger, the key difference is that the signature and public key were not part of the `scriptSig` prefix in the raw transaction. Instead, they are retrieved from the **Witness Vector**. This segregation allows for the "Witness Discount," making the transaction cheaper by counting witness bytes as only 0.25 bytes for weight calculations.

6 Part 3: Comparative Analysis and Reflection

6.1 Data-Driven Metric Comparison

The following table provides an empirical comparison of the metrics captured from the Legacy (P2PKH) and SegWit (P2SH-P2WPKH) transaction chains executed in the regtest environment. These values were extracted programmatically using the `decoderawtransaction` RPC method.

Metric	Legacy (Part 1)	SegWit (Part 2)	Difference
Physical Size (Total Bytes)	225 B	247 B	+22 B
Virtual Size (vSize)	**225 vB**	**166 vB**	**-59 vB**
Weight Units (WU)	**900 WU**	**661 WU**	**-239 WU**
Transaction Malleability	Vulnerable	**Fixed**	Protocol Security

Table 1: Comparative analysis of transaction footprint and network weight.

6.2 Technical Analysis and Reflection

The transition from Legacy to Segregated Witness (BIP 141) represents a fundamental shift in how the Bitcoin protocol handles data. Our results highlight three critical areas of improvement:

6.2.1 1. The Witness Discount and Block Capacity

A primary observation from the data is that the SegWit transaction is physically larger than the Legacy one (247 vs 225 bytes). This is due to the overhead of the SegWit *marker* and *flag* bytes, as well as the encapsulation of the P2WPKH witness program within a P2SH redeem script.

However, despite being physically larger, the **Virtual Size (vSize)** is 26% lower. This occurs because the signature data which occupied the majority of the space in the Part 1 `scriptSig` is moved to the **Witness Field**. Under BIP 141 rules, witness data is weighted at only 1 unit per byte, whereas base data is weighted at 4 units per byte. This "discount" allows for higher transaction throughput within the same block limits.

6.2.2 2. Script Execution and Stack Logic

Using the `btcdeb` debugger, we observed a significant change in the validation flow:

- **Legacy:** The engine concatenates the `scriptSig` and `scriptPubKey` to execute a single stack. The signatures are part of the transaction's "core," and any change to the signature bits results in a new hash (TXID).
- **SegWit (P2SH-wrapped):** The `scriptSig` now contains only a "Redeem Script" (`0014 <hash>`). The Bitcoin nodes recognize this as a version 0 witness program. The actual cryptographic verification (signatures and public keys) is performed using the data in the **Witness Stack**, which is kept separate from the data used to calculate the TXID.

6.2.3 3. Resolution of Transaction Malleability

The most profound security benefit observed is the fix for **Transaction Malleability**. In Part 1, the signature was part of the data hashed to generate the TXID. An attacker could intercept a transaction and alter the signature format (which does not invalidate the signature) to change the TXID, causing issues for unconfirmed transaction chains.

In our Part 2 implementation, moving the signature to the **Witness Field** ensures that changes to the signature data do not affect the TXID hash. This stability is the essential technical requirement for scaling solutions like the **Lightning Network**, where pre-signed, unbroadcasted transactions must have immutable identifiers to ensure funds can always be recovered.

7 Conclusion and Final Reflection

This lab provided a practical walkthrough of how Bitcoin transactions have evolved from Legacy to SegWit formats. By scripting the entire lifecycle of both P2PKH and P2SH-P2WPKH chains in a regtest environment, we were able to verify the specific technical trade-offs in size, security, and script execution that define the current Bitcoin architecture.

7.1 Key Technical Observations

- **Script Validation Logic:** Using `decoderawtransaction` and `btcdeb` was essential for seeing how the Bitcoin VM actually processes the stack. We confirmed that validity depends entirely on the challenge-response interaction between the `scriptSig` and `scriptPubKey`. Successfully broadcasting these transactions proved that our automated fee calculations and UTXO selections met the network's consensus rules.
- **Efficiency via the Witness Discount:** The data collected clearly shows the impact of the **Witness Discount**. Although the SegWit transactions had a larger raw byte count, their **Virtual Size (vSize)** was significantly lower. This confirms that segregating signature data is a highly effective way to pack more transactions into a block without hitting the legacy 1MB limit.

- **Impact on Malleability:** A major takeaway was observing how SegWit fixes **Transaction Malleability**. By moving signatures to the witness field, the TXID becomes immutable. This isn't just a minor fix it is what makes the Lightning Network and other Layer 2 protocols possible, as they require stable transaction identifiers to manage pre-signed state updates.

7.2 Final Summary

Completing this assignment helped bridge the gap between simple CLI commands and low-level RPC programming. Moving from basic address generation to manual raw transaction construction provided a much deeper understanding of how Bitcoin handles ownership and scaling. As the protocol moves toward newer standards like Taproot, the core concepts of script execution and witness segregation explored here will remain fundamental to any professional work in blockchain engineering.
